Abstract

We investigate the subgap spectrum and transport properties of the quantum dot on the interface between the metallic and superconducting leads and additionally side-coupled to the edge of the topological superconducting (TS) chain, hosting the Majorana quasiparticle. Due to the chiral nature of the Majorana states only one spin component of the quantum dot electrons (say ↑) is directly affected, however the proximity induced on-dot pairing transmits its influence on the opposite spin as well. We investigate the unique interferometric patterns driven by the Majorana quasiparticle that are different for each spin component. We also address the spin-sensitive interplay with the Kondo effect manifested at the same zero-energy and we come to the conclusion that quantum interferometry can unambiguously identify the Majorana quasiparticle.

Keywords: quantum interference, Majorana quasiparticles, spin-resolved Andreev spectroscopy

1. Introduction

Many-body effects can generate in condensed matter systems a plethora of either bosonic (like phonons, magnons) or fermionic quasiparticles (e.g. polarons). Recently enormous activity has been devoted to very exotic types of quasiparticles, resembling the Majorana fermions [4–8] that are identical with their own antiparticles. Such emergent quasiparticles appear under specific conditions in the symmetry broken states [1–3] and their non-Abelian character makes them of interest for quantum computing and/or brand new spintronic devices [9].

Realization of the Majorana quasiparticles has been predicted in various systems, for example in: vortices of superfluids [10], three-dimensional [11] or two-dimensional [12] topological insulators coupled to superconductors, noncentrosymmetric superconductors [13], electrostatic defects in topological superconductors [14], p-wave superconductors [15], the semiconducting [16, 17] or ferromagnetic [18] nanowires with the strong spin–orbit interaction coupled to s-wave superconductors, Josephson junctions [19], ultracold atom systems [20], and others. Experimental evidence for the Majorana quasiparticles has already been reported by the tunneling spectroscopy using the Rashba nanowires coupled to the bulk s-wave superconductors [21–24]. Zero-bias enhancement of the differential conductance observed at the edges of such wires [21–23] has been interpreted as the signature of the Majorana mode, but a similar feature can be eventually assigned to disorder [25], Kondo effect in a crossover from the doublet to singlet configurations [26, 27] or other effects [28].

For unambiguous identification of the Majorana quasiparticles there have been proposed several alternative methods, relying e.g. on optomechanical detection [29], shot noise measurements [30], Josephson spectroscopy [31] using heterostructures comprising the quantum dot (QD) side-attached to the nanowire (see figure 1). In the case when both external leads are metallic the reduction (by half) of the quantum dot conductance [32], the suppression of the Seebeck coefficient (due to perfect particle-hole symmetry at the Fermi level) [33]
and the unique interferometric lineshapes have been predicted [34–39].

T-shape setup, where QD is laterally coupled between the superconducting and metallic leads (figure 1) can reveal the fingerprints of Majorana fermions in the subgap spectrum [40]. This configuration was already addressed in the literature [40–42] but the spin-sensitive transport properties have not been analyzed in detail. Charge transport can occur at low voltage via the Andreev scattering, when electrons from the normal lead are converted into the Cooper pairs of superconductor reflecting the holes back to the same metallic electrode. Such spin-selective Andreev spectroscopy has been suggested for probing the vortices in topological superconductors [43, 44] and it has recently provided evidence for the Majorana modes in Bi₂Te₃/NbSe₂ [45].

Two normal quantum dots arranged in the same T-shape configuration (as shown in figure 1) have been earlier studied by us [46] and other groups [47–50]. These studies indicated that quantum interference effects are capable of probing an interplay between the electron paring (manifested by Andreev/Shiba states) and the strong correlations. Here we extend the previous analysis [46], by considering the influence of side-attached Majorana quasiparticle on the spin-resolved subgap spectrum of central QD and the transport properties. We show that Andreev transport would reveal interferometric lineshapes driven by the Majorana quasiparticles. Furthermore, we discuss how such interferometric features combine with the Kondo effect that is manifested at the same zero-energy.

The paper is organized as follows. In section 2 we formulate the microscopic model and study interferometric effects appearing in a subgap spectrum of the uncorrelated QD. Next, in section 3, we analyze the correlation effect for the Kondo regime. A summary and conclusions are listed in section 4. Some helpful technical details are presented in the appendices.

2. Formulation of the problem

Due to chiral properties the ends of topological superconducting wire, that host a pair of Majorana fermions, are spin polarized [51–53]. For this reason we assume that only one spin of the central quantum dot (QD) in the T-shape configuration (figure 1) is directly coupled to the Majorana quasiparticle [54]. When both electrodes are conducting the spin up and down transport channels are independent, at least in the absence of the correlations [55]. This is however no longer true, if one (or both) lead(s) is (are) superconducting, because of the proximity effect which mixes the particle with hole degrees of freedom [56, 57]. In consequence, any physical process that engages electrons of a given spin simultaneously affects its opposite spin partner [58]. Such a mechanism will prove to be important when considering the quantum interference driven by the side-coupled Majorana quasiparticle.

The previous study [46] indicated that electron pairing induced in the normal double quantum dot (DQD) on the interface between the metallic and superconducting electrodes is characterized by two lineshapes: Fano-type resonance formed near the energy ɛ₂ of the side-coupled quantum dot [59] and anti-Fano structure appearing at −ɛ₂ [46]. These features are detectable in the subgap Andreev conductance. In the present study we check whether similar effects appear when the central quantum dot is coupled to the Majorana quasiparticle, whose generic nature is related to only one spin (say ↑). For clarifying the interferometric lineshapes appearing in the spectrum of QD and the Andreev transport we briefly revisit the usual N-DQD-S heterostructure, imposing the spin polarized inter-dot hopping (appendix B). Such a consideration provides useful interpretation of the spin-dependent Fano and anti-Fano resonances.

2.1. Microscopic model

Tunneling structure, comprising the central QD embedded between the metallic and superconducting electrodes and side-coupled to the topological nanowire with the edge Majorana quasiparticles (figure 1), can be described by the Anderson-type Hamiltonian

\[ H = H_{\text{bath}} + \sum_{\beta=S,N} \epsilon_\beta |\bar{b}^\dagger_{\bar{b}}|\beta + H_{\text{QD}} + H_{\text{MQD}} \]  

(1)

The bath \(H_{\text{bath}} = H_N + H_S\) consists of the metallic \(H_N = \sum_{\alpha} |\bar{b}^\dagger_{\bar{b}}|\alpha C^\dagger_{\alpha N} C_{\alpha N}\) and superconducting \(H_S = \sum_{\beta} \xi_{\beta} C^\dagger_{\beta S} C_{\beta S} - \sum_{\alpha} (\Delta C^\dagger_{\alpha S} C_{\alpha S} + \text{h.c.})\) reservoirs, where electron energies \(\xi_{\beta}\) are measured from the chemical potentials \(\mu_{\beta}\). The central QD is described by \(H_{\text{QD}} = \sum_{\sigma} \epsilon \bar{b}^\dagger_{\bar{b}} d_{\sigma} d_{\sigma} + U n_{\bar{b}} n_{\bar{b}}\), where \(\epsilon\) denotes the energy level and \(U\) stands for the repulsive interaction between opposite spin electrons. QD is hybridized with the external reservoirs by \(H_{\text{T,} \beta} = \sum_{\sigma} \epsilon_{\sigma} V_{\beta \sigma} d_{\sigma} C_{\sigma \beta} + \text{h.c.}\), where \(V_{\beta \sigma}\) denote the matrix elements.
Focusing on a subgap regime (i.e. energies $|\omega| \ll \Delta$) it has been shown that the superconducting electrode induces the static pairing. Its role can be thus played by the proximized quantum dot $H_{\text{prox}} = \sum_{i} \epsilon_i d_i^\dagger d_i + U n_i n_i - \frac{\Gamma_2}{2} (d_i^\dagger + d_i^\dagger).$ This simplification is fairly acceptable for our considerations of the spin-dependent subgap spectrum and the Andreev spectroscopy. Low-energy theory of the Rashba nanowire can be expressed by[30]

$$H_{\text{MQD}} = i \epsilon_m n \eta \eta + \lambda (d_i^\dagger \eta_1 + \eta_1 d_i^\dagger),$$  (2)

where the operators $\eta_1 = \eta_i^1$ describe the edge states and $\epsilon_m$ accounts for their overlap. It is convenient to represent the exotic Majorana operators $\eta_1$, $\eta_2$ by the standard fermionic ones $[8]$ $\eta_1 = \frac{1}{\sqrt{2}} (f + f^\dagger)$, $\eta_2 = \frac{1}{\sqrt{2}} (f - f^\dagger).$ In this representation the term (2) takes the following form

$$H_{\text{MQD}} = t_m (d_i^\dagger - d_i)(f + f^\dagger) + \epsilon_m \left(f^\dagger f + \frac{1}{2}\right),$$  (3)

where $t_m = \lambda \sqrt{2}.$

\[ G_\tau(\omega) = \frac{1}{W} \begin{pmatrix} b_{mn} - 2 \tau^2 \omega & -D(b_{mn} - 2 \tau^2 \omega) & b_{mt} & b_{mt} \\ -D(b_{mn} - 2 \tau^2 \omega) & \frac{1}{\omega - \epsilon + i \Gamma/2} & D^\dagger(b_{mn} - 2 \tau^2 \omega) & -D_{bt} \\ b_{mt} & -D_{bt} & \bar{b}_{mn} \equiv -D_{bt} & b_{mt} \\ b_{mt} & b_{mt} & \bar{b}_{mn} \equiv -D_{bt} & -D_{bt} \end{pmatrix}, \]

where $W \equiv [abmn - 2 \tau^2 \omega(a + b)]$ and $D \equiv (\Gamma/2)(\omega + \epsilon + i \Gamma/2).$ In the same way, we also determined the matrix Green’s function $G_\tau(\omega).$ Below we present explicitly $G^{(11)}(\omega) = \langle \langle d_i^\dagger; d_i^\dagger \rangle \rangle$ which yields the spectral function of $\downarrow$ electrons. It takes the following form

$$G^{(11)}(\omega) = G_N(\omega) + \frac{\Gamma_2}{2} G_\tau(\omega)^2 \frac{abmn - 2 \tau^2 \omega}{abmn - 2 \tau^2 \omega(a + b)}.$$  (7)

$G_N(\omega) = \langle \langle d_i^\dagger; d_i^\dagger \rangle \rangle,$ is Green’s function for the case when QD is coupled only to the metallic lead (i.e. for $\Gamma_2 = 0 = t_m$).

Let us remark that differences between $G_\tau(\omega)$ and $G_N(\omega)$ originate from the fact that only spin $\uparrow$ electrons are directly coupled to the Majorana mode. This difference vanishes for $t_m \rightarrow 0$ when $G^{(11)}$ reproduce the result [62] obtained for the dot coupled only to N and S electrodes $\lim_{t_m \rightarrow 0} G^{(11)} = \left[\omega - \epsilon + i \Gamma/2 - \frac{\Delta^2/2^2}{\omega - \epsilon + i \Gamma/2}\right].$ On the other hand, for $t_m \neq 0$ in the absence of a superconducting electrode ($\Gamma_2 = 0$) the solution for spin $\downarrow$ electrons is identical with the solution for QD coupled only to normal metal, regardless of the coupling strength to TS wire. This is because spin $\downarrow$ electrons are not affected by the side-coupled Majorana quasiparticle (so without electron pairing they do not ‘feel’ any interference). This result clearly indicates that the interference patterns appearing in the spectrum of $\downarrow$ electrons originate solely from the pairing with electrons of the opposite spin.

### 2.2. Scattering on Majorana quasiparticles

Let us denote the particle and hole Green’s functions of the central QD coupled to the metallic and superconducting leads in the absence of the Majorana quasiparticle by $\langle \langle d_i^\dagger; d_i^\dagger \rangle \rangle \equiv \alpha^{-1}$ and $\langle \langle d_i^\dagger; d_i^\dagger \rangle \rangle \equiv \alpha^{-1}.$ For the uncorrelated case ($U = 0$) these functions read (B.2)

$$a = \omega - \epsilon + \frac{\Gamma_N}{2} = \left(\frac{\Gamma/2}{\omega + \epsilon + i \Gamma/2}\right),$$  (4)

$$b = \omega + \epsilon + \frac{\Gamma_N}{2} = \left(\frac{\Gamma/2}{\omega - \epsilon + i \Gamma/2}\right).$$  (5)

Similarly, we denote the inverse particle and hole propagators of the isolated Majorana quasiparticle by $\alpha \equiv (\omega - \epsilon_m)$ and $\eta \equiv (\omega + \epsilon_m),$ respectively.

Using the equation of motion approach (see appendix A) we calculated the Green’s function $G_{\tau}(\omega) = \langle \langle \Psi_\tau; \Psi_\tau^\dagger \rangle \rangle$ defined in the matrix notation $\Psi_\tau = (d_e, d_e^\dagger, f, f^\dagger).$ For spin $\uparrow$ Green’s function reads

\[ G_{\tau}(\omega) = \left(\begin{array}{cccc} b_{mn} - 2 \tau^2 \omega & -D(b_{mn} - 2 \tau^2 \omega) & b_{mt} & b_{mt} \\ -D(b_{mn} - 2 \tau^2 \omega) & \frac{1}{\omega - \epsilon + i \Gamma/2} & D^\dagger(b_{mn} - 2 \tau^2 \omega) & -D_{bt} \\ b_{mt} & -D_{bt} & \bar{b}_{mn} \equiv -D_{bt} & b_{mt} \\ b_{mt} & b_{mt} & \bar{b}_{mn} \equiv -D_{bt} & -D_{bt} \end{array}\right), \]

2.3. Deviation from usual Fano shape

In figure 2 we illustrate the spectral function $\rho_\tau(\omega)$ of the central QD weakly coupled to the Majorana quasiparticle, in the case $\epsilon_m = 0.$ Interference pattern appearing at $\omega = 0$ in the spectral function $\rho_\tau(\omega)$ resembles a resonant lineshape. However, from a careful examination we clearly notice that it is not really the true Fano resonance (like the one for $\uparrow$ electrons shown in figure B2). Such a line-shape indicates, that electron waves resonantly scattered by the Majorana quasiparticle (to be regarded as half of the physical electron) change their phase only by the fraction of $\pi$ (which is a typical value for scattering caused by the side-coupled ordinary quantum dots [59]). The mechanism responsible for this fractional interferometric feature has the same origin as $4\pi$-periodicity of the Josephson junctions made of two ‘majoranized’ superconducting wires [3, 17, 19, 31, 63].

In Rashba nanowires of a finite length the Majorana quasiparticles partly overlap with one another, inducing some energy splitting between the edge modes ($\epsilon_m \neq 0$). In figure 3 we show the interference patterns obtained for $\epsilon_m = \Gamma_N.$ Spectrum of the spin $\uparrow$ electrons reveals two fractional Fano-like resonances (solid line in figure 3), whereas the spin $\downarrow$ electrons are characterized by two anti-Fano features (dashed lines in figure 3) at the same energies. Let us emphasize, that such behavior is qualitatively different from the results for T-shape heterojunction with the ordinary quantum dot (figure B2).
Interferometric effects could thus be useful for detecting the Majorana quasiparticles in the presence of electron pairing.

2.4. Evolution to ‘molecular’ region

The interferometric Fano-like structures displayed in figures 2 and 3 occur when the central QD is very weakly coupled to the side-attached Majorana quasiparticle. Upon increasing the interdot coupling $t_m$, the nanoscopic (QD and MQD) objects can be expected to develop some new spectroscopic signatures, characteristic for the entire ‘molecular’ complex.

Evolution of the spectral function $\rho_\sigma(\omega)$ versus $t_m$ is presented in figure 4. For increasing $t_m$ we observe that two Andreev peaks (originating from the mixed particle and hole degrees of freedom [62]) and the Fano/anti-Fano line-shapes (caused by the Majorana QD) gradually change into the three-peak structure. In both spin components we clearly see the emergence of the zero-energy peak at the expense of reducing the spectral weight of the initial Andreev states. Formation of the zero-energy peak signifies a ‘leakage’ of the Majorana quasiparticle into the central QD, in analogy to what has been discussed in [54]. In the present case such proximity induced zero-energy state affects both spin sectors, despite the fact that MQD is directly coupled only to the spin $\uparrow$ electrons.

2.5. Majorana fingerprints in Andreev spectroscopy

Interference effects caused by the Majorana quasiparticle can be practically observed in our setup (figure 1) by measuring the tunneling current under nonequilibrium conditions $\mu_\text{NS} \neq 0$. When applied voltage $\mu_\text{NS} - \mu_\text{N} \equiv eV$ is smaller in magnitude than $\Delta$ the charge current $I_\text{ch}(V) = \sum_i I_{\text{Ai}}(V)$ is contributed by spin $\uparrow$ ($i \equiv 1$) and spin $\downarrow$ ($i \equiv 2$) electrons. The spin-dependent Andreev currents can be expressed in Landauer form

$$I_{\text{Ai}}(V) = \frac{e}{h} \int d\omega \ T_{\text{Ai}}(\omega) \left[ f(\omega - eV) - f(\omega + eV) \right],$$

where $f(x) = \frac{1}{1 + \exp(x/k_B T)}^{-1}$ is the Fermi distribution and transmittance for each spin sector

$$T_{\text{Ai}}(\omega) = \Gamma_D \times \begin{cases} \left\langle \langle d_i; d_i \rangle \right\rangle \times & \text{for } i = 1 \\ \left\langle \langle d_i; d_i \rangle \right\rangle \times & \text{for } i = 2 \end{cases}$$

 describes a probability of converting the electron with spin $\sigma$ into the hole with spin $\bar{\sigma}$ in the metallic lead. The differential conductance $G_{\text{Ai}}(V) = \text{d}I_{\text{Ai}}(V)/\text{d}V$ is enhanced near the subgap (Andreev/Shiba) states [62], but it is also sensitive to any other
obtained for \( \Gamma = 4 \Gamma_N \) and weakly hybridized with the side-attached Majorana quasiparticle \( e_m = 0.3 \Gamma_N \), where \( e_m = 0 \) (upper panel) and \( e_m = \Gamma_N \) (bottom panel). The red line refers to \( \uparrow \) and the blue one to \( \downarrow \) spin sectors.

of the subgap features, including the quantum interference effects [46].

Figure 5 shows the spin-resolved Andreev transmittance \( T_{\uparrow}(\omega) \) obtained for \( e_m = 0 \) (upper panel) and \( e_m = \Gamma_N \) (bottom panel). In the first case we observe the fractional resonance appearing for each spin sector at zero-bias (although of opposite shapes). In the case \( e_m = 0 \) we notice two interferometric structures at \( \epsilon V = \pm \epsilon_m \). For spin \( \uparrow \) sector there appears the pronounced resonance at \( \epsilon V = \epsilon_m \) and another shallow structure at \( \epsilon V = -\epsilon_m \). The Andreev transmittance of \( \downarrow \) sector has an opposite shape, i.e. \( T_{\downarrow}(\omega) = T_{\uparrow}(-\omega) \). The spin-resolved Andreev transport could thus estimate the overlap \( \epsilon_m \) between the edge modes of TS nanowire. For \( e_m = 0 \) such spectroscopy can distinguish the fractional interferometric lineshapes caused by the Majorana quasiparticle from the typical Fano/antiFano lineshapes due to the normal quantum dots (see appendix B).

3. Correlation effects

Since the interferometric feature caused by the side-attached Majorana quasiparticle shows up at the Fermi level (for the case \( e_m = 0 \) it is natural to inspect its relationship with the Kondo effect, whose signature (narrow peak) appears at the same energy. The many-body Kondo effect occurs at low temperatures due to the effective exchange interaction induced between the QD and normal lead (N) electrons. Its subtle nature in a subgap regime has been addressed by a variety of methods (see the recent discussion [26, 27] and other references cited therein).

3.1. Methodological details

In the present context we shall treat the correlations using the decoupling scheme for Green’s functions [46] that proved to be satisfactory on a qualitative level [64]. To account for the Kondo effect we start from the results obtained for the uncorrelated problem (section 2) and proceed with approximations for the electron–electron interactions. In the absence of the side-attached MQD, we again introduce the abbreviations for particle \( \langle \langle d_1^\dagger; d_2^\dagger \rangle \rangle \equiv a^{-1} \) and hole \( \langle \langle d_1^\dagger; d_2 \rangle \rangle \equiv b^{-1} \) propagators. Following our previous study [62] of the single quantum dot (N-QD-S) setup we approximate these propagators by

\[
\tilde{a} = \omega - \epsilon - \Sigma_N(\omega) + \frac{(\Gamma_N/2)^2}{\omega + \epsilon + [\Sigma_N(-\omega)]^*},
\]

\[
\tilde{b} = \omega + \epsilon + [\Sigma_N(-\omega)]^* + \frac{(\Gamma_N/2)^2}{\omega - \epsilon - \Sigma_N(\omega)},
\]

where the selfenergy \( \Sigma_N(\omega) \) accounts for the coupling of QD to the normal lead, taking into account the interactions between electrons \( Un_{\uparrow \downarrow} \).

We approximate \( \Sigma_N(\omega) \) using the popular decoupling scheme for Green’s functions (discussed in appendix B of [46]) which yields

\[
\tilde{G}_N(\omega) \equiv \frac{1}{\omega - \epsilon - \Sigma_N(\omega)} = \frac{1}{\omega - \epsilon - U(1 - \langle n_N \rangle) - \Sigma_N(\omega)}.
\]

where

\[
\Sigma_N(\omega) = \sum_k |V_{kN}|^2 \left[ \frac{f(\xi_{kN})}{\omega - \xi_{kN}} + \frac{f(\xi_{kN})}{\omega + \xi_{kN}} \right].
\]

Alternatively one can treat the correlation effects at the central quantum within more sophisticated methods [55].

Substituting the inverse Green’s functions (10) and (11) with the selfenergy \( \Sigma_N(\omega) \) to the matrix Green’s function (6) we obtain

\[
\tilde{G}_N^{(1)}(\omega) = \tilde{G}_N(\omega) + \left[ \frac{\Gamma}{2} \tilde{\Sigma}_N(\omega) \right] \tilde{\omega} + \frac{2 \tilde{\omega}^2 - 2 \tilde{\omega} \epsilon}{W},
\]

where

\[
G_{N=1}(\omega) = \tilde{G}_N(\omega) + \left[ \frac{1}{2} \tilde{\Sigma}_N(\omega) \right] \tilde{\omega} + \frac{2 \tilde{\omega}^2 - 2 \tilde{\omega} \epsilon}{W}.
\]

In our setup the correlated quantum dot is connected to the superconducting reservoir, which (by proximity effect) induces the on-dot electron pairing. On the other hand, the repulsive Coulomb interactions disfavor any double occupancy, suppressing the local pairs. Even though the pairing
and correlations are strongly antagonised one can find some regime of the model parameters, for which the Kondo physics coexists with the on-dot pairing [27] (the latter is necessary for activating the Andreev tunnelling that could probe the subgap states). This regime is particularly important if we want to confront the Kondo state with the interferometric structures due to side-attached Majorana quasiparticle.

Optimal conditions where the Kondo effect coexists with the on-dot pairing can be tuned by \( \varepsilon \) (that controls QD occupancy) and the ratio between couplings to external electrodes \( \Gamma_{\text{SN}}/\Gamma_Y \) (that is crucial for the effective exchange potential [27]). For specific calculations we focus here on the strong Coulomb potential \( U = 25\Gamma_Y \) and choose \( \varepsilon = -21\Gamma_Y \). We have checked that in such a situation the Kondo effect coexists with the on-dot pairing for slightly asymmetric couplings \( \Gamma_Y \in (2\Gamma_Y, 6\Gamma_Y) \). With this in mind, we thus fixed the ratio \( \Gamma_{\text{SN}}/\Gamma_Y = 4 \). In the absence of MQD (i.e. for N-QD-S configuration) the narrow Kondo peak at \( \omega = 0 \) coexists then with the subgap Andreev quasiparticle peaks at \( \omega \approx \pm \sqrt{\varepsilon^2 + (\Gamma_{\text{SN}}/2)^2} \) whose broadening (inverse life-time) is proportional to \( \Gamma_Y \) [62].

3.2. Majorana versus Kondo feature

Influence of the side-coupled Majorana quasiparticle on the spin-resolved spectral functions \( \rho_{\sigma}(\omega) \) of the correlated QD is illustrated in figures 6 and 7. The upper panels correspond to the case of overlapping Majorana modes \( \epsilon_m = \Gamma_Y \). In analogy to the noninteracting situation (figure 3) we observe the fractional Fano and anti-Fano lineshapes appearing at \( \omega = \pm \epsilon_m \) in the spectrum of spin \( \uparrow \) and \( \downarrow \) electrons, respectively. For \( \downarrow \) electrons we also notice that both anti-Fano resonances are much less pronounced as compared to \( U = 0 \) case. This is a consequence of the strong Coulomb interactions suppressing the on-dot pairing, that is indirectly responsible for the interferometric structures in the spectrum of \( \downarrow \) electrons.

The most intriguing case occurs for \( \epsilon_m = 0 \), when the Kondo and interferometric structures coincide at exactly the same energy. Spectrum of \( \uparrow \) electrons, that are directly coupled to the Majorana quasiparticle clearly show the dominant and destructive influence of the quantum interference on the Kondo state (see the bottom panel in figure 6, where the Kondo peak is completely washed out). As regards the spectrum of \( \downarrow \) electrons, the anti-Fano interferometric structure constructively combines with the Kondo peak, enhancing the zero-energy feature.

Scattering mechanism driven by the zero-energy Majorana quasiparticle side-attached to the correlated quantum dot has thus a very interesting effect on the Kondo state. For the spin \( \uparrow \) sector (directly coupled to the Majorana quasiparticle) the ongoing quantum interference has destructive character. In other words, the fractional Fano-type resonance induced by the side-coupled Majorana quasiparticle is robust against the Kondo peak. In contrast, in the spin \( \downarrow \) sector (where electrons are not directly coupled to the Majorana quasiparticle) the Kondo state is promoted by the quantum interference. Such exotic spin-resolved quantum interference effects might be useful for experimental detection of the Majorana quasiparticle.
quasiparticle. From a physical point of view, this spin-resolved screening effects of the correlated quantum dot is due to the following mechanism: the spin ↑ electrons ‘leak’ into the side-coupled Majorana structure (hence there is less spin ↑ to be screened), whereas the on-dot pairing compensates such loss by enhancing the density of ↓ electrons whose screening is effectively pronounced.

Practical observation of the Majorana and Kondo signatures would be feasible only indirectly, by measuring a differential conductance $G_{\text{K}} = dI(V)/dV$ of the net subgap current (8). Since both effects appear at zero energy, they should be manifested in the linear conductance (i.e. at $V = 0$). In the absence of the side-attached Majorona quasiparticle (blue line in figure 8) we indeed observe a zero-bias enhancement driven by the subgap Kondo effect, that has been reported experimentally by several groups [65–68]. For the case, when Majorana quasiparticle is side-coupled to the interfacial QD (red line in figure 8) there appears the dip at $V = 0$ instead of the previous enhancement. Such a destructive effect could thus distinguish between the Kondo and Majorana features. Furthermore, in realistic situation the magnetic field (which is necessary for inducing the zero-energy mode of TS wire) would additionally split the Kondo resonance, shifting it from $V = 0$. In the configuration discussed here the zero-bias dip caused by the Majorana quasiparticle is hence robust against the eventual spectroscopic feature of the Kondo effect.

4. Summary

We studied interferometric structures induced by the Majorana quasiparticle side-coupled to the quantum dot on the interface between the superconducting and normal electrodes. Due to the superconducting proximity effect such lineshapes appear simultaneously in both spin sectors, even though only one of the spins is directly coupled to the Majorana state. For each spin component, however, they are manifested differently.

The subgap spectrum of ↑ electrons (directly coupled to the Majorana quasiparticle) is characterized by the fractional Fano-type lineshapes. Their fractionality is caused by the fact that Majorana quasiparticle is half of a true electronic state. On the other hand, the spectrum of opposite spin electrons is characterized by anti-Fano lineshapes appearing at the same energies as for ↑ electrons. Such quantum interference does effectively yield different (spin-resolved) Andreev transmittances.

We also confronted the spin-resolved interferometric features with the Kondo effect (caused by the strong correlations). We found that the side-coupled Majorana quasiparticle can either suppress or enhance the Kondo effect, depending on the spin orientation. Screening of electrons that are directly coupled to the Majorana quasiparticle is practically destroyed by the quantum interference, whereas for the opposite spin component reveals substantial enhancement of the Kondo peak. We hope that our results can stimulate experimental efforts to verify the spin-selective influence of the Majorana quasiparticles on the Kondo state.

Appendix A. Derivation of Green’s functions

In this appendix we outline the procedure for determination of the matrix Green’s function (6). Starting from the model Hamiltonian (1) we consider the uncorrelated quantum dot $U = 0$ coupled between the metallic (N) and superconducting (S) electrodes and additionally side-coupled to the edge of topological wire. In the deep subgap regime the superconducting electrode induces the static on-dot pairing and (1) simplifies to

$$H = H_N + H_{r,N} + \frac{\Gamma_S}{2} \{d_i^T d_i + d_i d_i^T\} + \sum_s \epsilon_s d_s^T d_s$$

$$+ t_m (d_i^T - d_i) (f^T + f) + \epsilon_m (f^T f + 1/2). \quad (A.1)$$

Fourier transform of the retarded Green’s function can be computed from the equation of motion $\omega \langle\langle A; B\rangle\rangle = \langle\langle [A, H], B\rangle\rangle + \langle\langle [A, H], B\rangle\rangle$ where $\pm$ denote anticommutator/commutator, respectively. The particle propagator $\langle\langle d_i^T d_i\rangle\rangle$ for spin ↑ electrons of the central QD is mixed with the operators of TS wire and with the anomalous Green’s function

$$\left(\omega - \epsilon + i \frac{\Gamma_S}{2}\right) \langle\langle d_i^T d_i\rangle\rangle = 1 - \frac{\Gamma_S}{2} \langle\langle d_i^T d_i\rangle\rangle$$

$$+ t_m \langle\langle f^T f + 1/2\rangle\rangle \quad (A.2)$$

As ↓ electrons are not directly coupled to TS wire the anomalous Green’s function $\langle\langle d_i^T d_i\rangle\rangle$ does not generate any propagator containing $f$ operators. Using EOM, it can be expressed via the hole propagator.
\[
\left(\omega + \epsilon + \frac{\Gamma_N}{2}\right)\langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle = -\frac{\Gamma_S}{2}\langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle \quad \text{(A.3)}
\]

Using (A.3) we can rewrite equation (A.2) as
\[
\left(\omega - \epsilon + \frac{\Gamma_N}{2} - \frac{(\Gamma_M/2)^2}{\omega + \epsilon + i\Gamma_N/2}\right)\langle \langle f_i^\dagger; f_i^\dagger\rangle\rangle
= 1 + t_m\langle \langle f_i^\dagger; d_i^\dagger\rangle\rangle + t_m\langle \langle f_i^\dagger; d_i^\dagger\rangle\rangle. \quad \text{(A.4)}
\]

We can notice that the expression in the bracket on the left hand side is the inverse particle propagator for N-QD-S system in the absence of the TS wire. For brevity we denote it by symbol \( a \), that is presented in equation (4).

The other Green’s functions, where \( d_i^\dagger \) is mixed with \( f \) and \( f^\dagger \) operators can be found from the EOM as
\[
(\omega - \epsilon_m)\langle \langle f_i^\dagger; d_i^\dagger\rangle\rangle = t_m\langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle - t_m\langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle, \quad \text{(A.5)}
\]
\[
(\omega + \epsilon_m)\langle \langle f_i^\dagger; d_i^\dagger\rangle\rangle = t_m\langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle - t_m\langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle. \quad \text{(A.6)}
\]

Equations (A.5) and (A.6) generate the new anomalous function \( \langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle \). We write down the equation of motion for this function
\[
\left(\omega + \epsilon + \frac{\Gamma_N}{2}\right)\langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle = \frac{\Gamma_S}{2}\langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle - t_m\langle \langle f_i^\dagger; d_i^\dagger\rangle\rangle + t_m\langle \langle f_i^\dagger; d_i^\dagger\rangle\rangle \quad \text{(A.7)}
\]
and determine the new function \( \langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle \) as
\[
\left(\omega - \epsilon + \frac{\Gamma_N}{2}\right)\langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle = \frac{\Gamma_S}{2}\langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle. \quad \text{(A.8)}
\]

Now the propagator \( \langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle \) can be represented as
\[
\left(\omega + \epsilon + i\Gamma_N/2 - \frac{(\Gamma_M/2)^2}{\omega + \epsilon + i\Gamma_N/2}\right)\langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle
= -t_m\langle \langle f_i^\dagger; d_i^\dagger\rangle\rangle + t_m\langle \langle f_i^\dagger; d_i^\dagger\rangle\rangle. \quad \text{(A.9)}
\]

Expression appearing in a bracket on the left hand side is the inverse hole propagator of N-QD-S system without TS wire. We have denoted it by symbol \( b \) in the main text, that is explicitly given by equation (5).

Finally, we obtain the following set of equations
\[
a\langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle = 1 + t_m\langle \langle f_i^\dagger; d_i^\dagger\rangle\rangle + t_m\langle \langle f_i^\dagger; d_i^\dagger\rangle\rangle,
\]
\[
b\langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle = -t_m\langle \langle f_i^\dagger; d_i^\dagger\rangle\rangle - t_m\langle \langle f_i^\dagger; d_i^\dagger\rangle\rangle,
\]
\[
(\omega - \epsilon_m)\langle \langle f_i^\dagger; d_i^\dagger\rangle\rangle = t_m\langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle + t_m\langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle,
\]
\[
(\omega + \epsilon_m)\langle \langle f_i^\dagger; d_i^\dagger\rangle\rangle = t_m\langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle - t_m\langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle.
\]

Expression appearing in a bracket on the left hand side is the inverse particle propagator for N-QD-S system in the absence of the TS wire. We have denoted it by symbol \( a \), that is presented in equation (4).

The entire matrix presented in equation (6) can be obtained by solving 4 similar sets of the equations.

### Appendix B. Spin-dependent coupling to normal QD

To distinguish the consequences caused by the fact that tunneling to the MQD involves only the spin \( \uparrow \) electrons from other effects due to their specific Majorana-type nature we examine here the setup in which TS is replaced by the usual quantum dot (QD).

\[
H_{\text{MQD}} \rightarrow H_{\text{QD}_i} = \sum_\sigma \epsilon_2^i d_i^{\dagger}\sigma d_i^\sigma + \sum_\sigma t_s^i d_i^{\dagger}\sigma d_{i+1}^\sigma + = \sum_\sigma t_s^i d_i^{\dagger}\sigma d_{i+1}^\sigma + h.c.. \quad \text{(B.1)}
\]

Our previous study [46] of such normal double quantum dot (DQD) in the T-shape configuration has been done for the spin independent couplings \( t_1 = t_2 \). Under such circumstances we have obtained the Fano and anti-Fano resonances, schematically displayed in figure B1.

In this appendix we address the spin-polarized coupling \( t_1 \neq t_2 \) focusing on the limit of vanishing \( t_2 \). Fourier transform of the retarded Green’s function for the uncorrelated central quantum dot is expressed by [46]

\[
\left[\langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle \langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle \langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle \langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle\right] = \left(\omega - \epsilon + \frac{\Gamma_N}{2} - \frac{\Gamma_M}{2}\right)^{-1}
= -\frac{\Gamma_S}{2} + \frac{\Gamma_N}{2} - \frac{\Gamma_M}{2} \quad \text{(B.2)}
\]

where \( \hat{\sigma} \) is inverse spin to \( \sigma \). For the weak identical couplings \( t_1 = t_2 \) the spectral function of central quantum dot \( \rho_\sigma(\omega) = -\pi \mathrm{Im}\left[\langle \langle d_i^\dagger; d_i^\dagger\rangle\rangle\right] \) is characterized by two interferometric structures at the QD level and on the opposite side of a Fermi level [46]. The feature at \( \omega = \epsilon_2 \) has the usual Fano-type resonant lineshape [59], whereas its companion at \( -\epsilon_2 \) has anti-resonant (antiFano) shape. Obviously for \( t_1 = t_2 \), the spectral functions \( \rho_\sigma(\omega) \) of both spins are identical.

When the tunneling of \( \downarrow \) electrons is forbidden (\( t_1 = 0 \)), the toy model (B.1) is closely analogous to the original setup (figure 1) with only spin \( \uparrow \) of the central quantum dot coupled to TS wire. In such case there survives the single interferometric structure in each of the spectral functions \( \rho_\sigma(\omega) \). For \( \uparrow \) electrons (directly coupled to the side-attached dot) we observe the Fano-type interference pattern at \( \epsilon_2 \) and for the opposite spin \( \downarrow \) electrons there appears the anti-Fano structure at \( -\epsilon_2 \). This result can be understood if we anticipate that the anti-Fano feature is an indirect response of the spin \( \uparrow \) electrons. In other words, even though the spin \( \downarrow \) electrons are not directly coupled to the side-attached quantum dot, due to the induced local pairing they ‘feel’ a feedback from the opposite (\( \uparrow \)) spin electrons.
The upper panel in figure B2 illustrates the spin-resolved spectral functions of the uncorrelated central quantum dot asymmetrically coupled to the normal QD2 whose energy level is $\epsilon_0^2$, where interferometric features appear either in the particle or hole regions. The bottom panel in figure B2 corresponds to the situation with $\epsilon_2 = 0$. In this case the Fano and anti-Fano lineshapes appear at the same position what is partly similar to the case with Majorana quasiparticle.

Figure B3 shows the spectral function $\rho_\sigma(\omega)$ obtained fairly below the Kondo temperature $T_K$ for spin $\uparrow$ (red line) and $\downarrow$ (blue line) electrons. The approximation described in section 3.1 cannot reliably reproduce the low energy structure of the Kondo peak $\omega \sim k_B T_K$, therefore our results should be treated only qualitatively.

The upper panel in figure B2 illustrates the spin-resolved spectral functions of the uncorrelated central quantum dot asymmetrically coupled to the normal QD2 whose energy level is $\epsilon_2 = 0$, where interferometric features appear either in the particle or hole regions. The bottom panel in figure B2 corresponds to the situation with $\epsilon_2 = 0$. In this case the Fano and anti-Fano lineshapes appear at the same position what is partly similar to the case with Majorana quasiparticle.

In the case when $\epsilon_2$ is far from the Kondo peak (top panel) we observe that the Fano-type resonance (seen in $\rho_\uparrow(\omega)$ at $\epsilon_2$) and its anti-Fano companion (present in $\rho_\downarrow(\omega)$ at $-\epsilon_2$) practically coexist with the zero-energy Kondo peak. The situation changes dramatically, when energy $\epsilon_2$ coincides with the Fermi level (bottom panel). In both spin sectors the Kondo peak is then completely destroyed by the interferometric lineshape.

Figure B1. Schematic view of the Fano and anti-Fano interference patterns induced in the T-shape setup with both normal quantum dots for $t_1 = t_2$.

Figure B2. Spectral function $\rho_\sigma(\omega)$ of the uncorrelated QD asymmetrically coupled ($t_1 = 0.3\Gamma_N, t_2 = 0$) to the normal QD2. The solid (red) line refers to $\uparrow$ electrons and the dashed (blue) ones to $\downarrow$ electrons. The results are obtained for the model parameters $\Gamma_N = 3\Gamma_N, \epsilon = -0.5\Gamma_N$ and $\epsilon_2 = 0$. We notice the usual Fano-type pattern for $\uparrow$ electrons (directly coupled to QD) accompanied by the anti-Fano feedback for spin $\downarrow$ electrons (due to the on-dot pairing). Top panel refers to $\epsilon_2 = -0.5\Gamma_N$ and the bottom one to $\epsilon_2 = 0$.

Figure B3. Spectral function the correlated QD side-coupled to the normal QD2 obtained for $I_3 = 4\Gamma_N, U = 15\Gamma_N, k_B T = 0.005\Gamma_N$. The solid (blue) line refers to $\uparrow$ and the dashed (red) line to $\downarrow$ electrons. Top panel refers to $\epsilon_2 = 0.5\Gamma_N$ and the bottom one to $\epsilon_2 = 0$. The solid (blue) line refers to $\uparrow$ and the dashed (red) line to $\downarrow$ electrons. Top panel refers to $\epsilon_2 = 0.5\Gamma_N$ and the bottom one to $\epsilon_2 = 0$.

Figure C1. Schematic view of STM-type configuration, where transport can occur between the normal tip (N) and the superconducting (Sc) substrate via the central quantum dot (QD1) which is laterally coupled to another quantum dot (QD2). Both dots absorb the $s$-wave (trivial) pairing.
This effect proves that the quantum interference is dominant, whenever it coincides with the Kondo peak. Let us notice that such tendency is distinct from the interferometric features induced by the Majorana quasiparticle (figures 6 and 7).

Appendix C. Influence of the trivially paired dot

In analogy to appendix B, we consider now the side-attached quantum dot QD2 characterized by the usual s-wave pairing. Physically such situation can be achieved in STM-type configuration illustrated by figure C1. The charge transport would occur between the normal tip (N) and the superconducting lead (Sc) through the quantum dot (QD1) deposited on superconductor and laterally coupled to another quantum dot (QD2), that rests on the same superconducting substrate. This setup can be described by the model similar to (B.1) with the s-wave pairing imposed on QD2. Formally we use the following model

\[ H_{QD2} = \sum_{\sigma} \epsilon_d d_{d^\sigma} d_{d^\sigma} - \left( \frac{\Delta}{2} d_2 d_2^\dagger + \text{h.c.} \right) + \sum_{\sigma} t d_{d^\sigma} d_{d^\sigma} + \text{h.c.}, \]

where \( \Gamma_2 \) describes the effective coupling of QD2 to the s-wave superconducting reservoir.

The key difference between the TS wire (that hosts the Majorana mode) and the QD2 (that absorbs the usual s-wave superconductivity) can be observed in the electronic spectra. Majorana quasiparticle emerges at \( \omega = 0 \), whereas the fermionic Shiba/Andreev states of QD2 are formed at finite energies \( \omega = \pm \sqrt{\epsilon_d^2 + (\Gamma_2/2)^2} \). Influence of QD2 on the subgap spectrum of the central QD1 is visible away from the Fermi level. Figure C2 presents the spectral function \( \rho_0(\omega) \) of QD1. As a matter of fact, its electronic spectrum qualitatively differs from the unique features due to Majorana quasiparticle, discussed in the main part of this work (see figure 2).
